Abstract

The Iterated Prisoner's Dilemma is a model for rational and evolutionary interactive behaviour. It has applications both in the study of human social behaviour as well as in biology.

This game is used to understand when and how a rational individual might accept an immediate cost to their own utility for the direct benefit of another.

Much attention has been given to a class of strategies for this game, called Zero Determinant strategies. It has been theoretically shown that these strategies can “extort” any player.

In this work, an approach to identify if observed strategies are playing in a Zero Determinant way is described. Furthermore, experimental analysis of a large tournament with 204 strategies is considered. In this setting the most highly performing strategies do not play in a Zero Determinant way. This suggests that whilst the theory of Zero Determinant strategies indicates that memory is not of fundamental importance to the evolution of cooperative behaviour, this is incomplete.

1 Introduction

Agent based game theoretic models have become a stalwart of the underpinning mathematics of interactive behaviours. Arguably, one of the major pieces of work in this area is the pair of original computer tournaments run by Robert Axelrod [2, 3]. This tournaments pitted submitted computer strategies against each other in plays of the Iterated Prisoner's Dilemma. A common game where agents can choose to pay a slight cost to their immediate utility in the hope of building a reputation. This has been used in economic and evolutionary game theory to understand the evolution of cooperative behaviour.

Recently, a class of strategies was described in [9] that can provably extort any given opponent. In [5, 7] some questions have already been asked about the true effectiveness of these strategies in an evolutionary setting. Here another question is asked: is it possible to recognise this extortionate behaviour? A mathematical procedure for suspicion is presented: in the same way that the continued actions of an extortionate individual might raise suspicion.

This work makes use of the Axelrod Python library [8, 6] with a large number of Prisoner Dilemma strategies available to give an extensive numerical example of the ideas presented.

The approach is presented in Section 2. All of the code and data discussed in Section 3 is open sourced, archived and written according to best scientific principles [12].

2 Recognising Extortion

In [9], given a match between 2 memory-one strategies, the concept of Zeto-Determinant (ZD) strategies is introduced. The main result of that paper showed that given two players $p, q \in \mathbb{R}^2$ a linear relationship between the players' scores could be forced by one of the players.

Assuming the utilities for player p are given by $S_x = (R, S, T, P)$ and for player q by $S_y = (R, T, S, P)$ and that the stationary scores of each player is given by S_X and S_Y respectively. The main result of [9] is that if

$$\tilde{p} = \alpha S_x + \beta S_y + \gamma \tag{1}$$

or

$$\tilde{q} = \alpha S_x + \beta S_y + \gamma \tag{2}$$

where $\tilde{p} = (1 - p_1, 1 - p_2, p_3, p_4)$ and $\tilde{q} = (1 - q_1, 1 - q_2, q_3, q_4)$ then:

$$\alpha S_X + \beta S_Y + \gamma = 0 \tag{3}$$

Here, the reverse problem is considered: given a $p \in \mathbb{R}^4$ how does one identify α, β, γ if they exist.

To do this, equation 1 is expressed linear algebraically as:

$$Mx = \tilde{p} \quad x = (\alpha, \beta, \gamma) \quad (4)$$

with $M \in \mathbb{R}^{4 \times 3}$ given by:

$$M = \begin{bmatrix} R & R & 1 \\ S & T & 1 \\ T & S & 1 \\ P & P & 1 \end{bmatrix} \quad (5)$$

Note that in general, equation (4) will not necessarily have a solution. From the Rouch-Capelli theorem if there is a solution it is unique as $\text{rank}(M) = 3$ which is the dimension of the variable x). Furthermore, removing a single row of M would ensure that the corresponding matrix is invertible. This corresponds to the fact that a ZD strategy is defined by only 3 of its values.

As an example, consider the known ZD strategy $p = (8/9, 1/2, 1/3, 0)$ from [10] which is referred to as **Extort-2**. In the standard case of $(R, S, T, P) = (3, 0, 5, 1)$ the inverse of $M_{(4)}$ (removing the last row of M) is given by:

$$M_{(4)}^{-1} = \begin{bmatrix} 1 & -\frac{3}{5} & -\frac{2}{5} \\ 1 & -\frac{3}{5} & -\frac{3}{5} \\ -5 & 3 & 3 \end{bmatrix} \quad (6)$$

The $x = (\alpha, \beta, \gamma)$ that corresponds to \tilde{p} is given by:

$$x = M_{(4)}^{-1} \tilde{p}_{(4)} = \begin{bmatrix} \frac{1}{18} & -\frac{1}{9} & \frac{1}{18} \end{bmatrix} \quad (7)$$

Using (4) gives that these values lead to the correct value for $p_4 = 0$ which confirms that p_4 is a ZD strategy.

This approach could in fact be used to confirm that a given strategy is acting in a ZD manner even if it is not a memory one strategy. However, in practice, if a closed form for p is not known, then due to measurement and/or numerical error this would not work.

Thus, an approach based on least squares [4] is proposed. This approach finds the best fitting $\bar{x} = (\bar{\alpha}, \bar{\beta}, \bar{\gamma})$ which minimises:

$$\text{SSError} = \|Mx - \tilde{p}\|_2^2 = \sum_{i=1}^4 ((M\bar{x})_i - \tilde{p}_i)^2 \quad (8)$$

Note that SSError, which is the square of the Frobenius norm [4], becomes a measure of how close a strategy is to being a ZD strategy.

In [9] a particular type of ZD is defined, if:

$$P(\alpha + \beta) + \gamma = 0 \quad (9)$$

then the player can ensure they get a score χ times larger than the opponent. This extortion coefficient is given by:

$$\chi = \frac{-\beta}{\alpha} \quad (10)$$

Thus, if (9) holds and $\chi > 1$ a player is said to extort their opponent. Recalling (5), equation (9) corresponds to the last row of M , thus a player p extorts their opponent if and only if $p_4 = 0$ and the estimated $\chi > 1$. Using the method of least squares, the strategy can be considered ZD for a given threshold of SSError and χ can be approximated. Figure 1 illustrates this for potential strategies: for all of these we see that for the strategy to be extortionate p_2 and p_3 seem to have a linear relationship: for example if $p_1 = 1$ and $p_4 = 0$ then all strategies where $p_2 = p_3$ are extortionate.

By observing interactions (human or otherwise), the transition rates of given players, their memory one representation can be approximated and this approach can be used to recognise extortionate behaviour. Immediately it is noted that if the environment is noisy [13] then no strategy can be considered to be extortionate as $p_4 > 0$.

In the next section, this idea will be illustrated by observing the interactions that take place in a computer based tournament of the IPD.

Figure 1: Strategies of the form: $p = (p_1, p_2, p_3, 0)$. The solid line shows the values for which $\text{SSError} < 10^{-6}$. Only values for which $\chi > 1$ are displayed, strategies outside of this region can never be extortionate.

3 Numerical experiments

In [10] results from a tournament with 19 strategies, was presented with specific consideration given to ZD strategies. This tournament is reproduced here using the Axelrod-Python project [6]. To obtain a good measure of the corresponding transition rates for each strategy all matches have been run for 2000 turns and every match has been repeated 60 times.

Using the pair wise interactions the transition rates p, q can be measured and the steady state probabilities inferred and compared to the actual probabilities of each state. This is done numerically by computing the singular eigenvector of the matrix: A [11]:

$$A = \begin{bmatrix} p_1 q_1 & p_1(1 - q_1) & (1 - p_1)q_1 & (1 - p_1)(1 - q_1) \\ p_2 q_2 & p_2(1 - q_2) & (1 - p_2)q_2 & (1 - p_2)(1 - q_2) \\ p_3 q_3 & p_3(1 - q_3) & (1 - p_3)q_3 & (1 - p_3)(1 - q_3) \\ p_4 q_4 & p_4(1 - q_4) & (1 - p_4)q_4 & (1 - p_4)(1 - q_4) \end{bmatrix}$$

Figure 2 shows a regression line fitted to every pairwise interaction with a reported R^2 value (pairwise interactions with missing states were omitted). This serves to validate the approach: a part from some edge cases the relationship is consistent.

Figure 3 shows the SSError values for all the strategies in the tournament, as reported in [10] the extortionate strategy (which has an expected SSError approximately 0) gains a large number of wins. Whilst [10] described the performance of each strategy, this approach also informs the behaviour of a strategy when their opponent is not a memory one strategy thus not creating a Markov chain.

Here, the work of [10] is extended by investigating a tournament with 204 strategies.

The results of this analysis are shown in Figure 4. The top ranking strategies by number of wins seem to be extortionate (but not against all strategies) and it can be seen that a small sub group of strategies achieve mutual defection. The top ranking strategies according to score all achieve mutual cooperation and do not extort each other, however they **do** extort a number of the lower ranking strategies.

4 Conclusion

This work defines an approach to measure whether or not a player is playing a strategy that corresponds to an extortionate strategy as defined in [9]. Indeed Figure 1 classifies all extortionate strategies. This is done through a linear algebraic approach for approximating the solution of a linear system. Using this, a very large number of pairwise interactions is simulated and in fact very few strategies are found to act extortionately.

Figure 2: The relationship between the steady state probabilities inferred from the measured transitions and the actual steady state probabilities. A linear regression line is included validating the approach.

Figure 3: SSError for the strategies of [10], ordered both by number of wins and overall score. Cooperator and Defector are omitted as they do not visit all the states.

Figure 4: SSError for the strategies for the full tournament. Only strategy interactions for which $p_4 = 0$ and $\chi > 1$ are displayed.

The work of [9], whilst showing that a clever approach to taking advantage of another memory one strategy exists: this is incomplete. Whilst the elegance of this result is very attractive, just as the simplicity of the victory of Tit For Tat in Axelrod’s original tournaments was, it is incomplete. Whilst extortionate strategies achieve a high number of wins they do not achieve a high score which corresponds to the fitness landscape in an evolutionary sense. This confirms the findings of [7] in which sophisticated strategies resist evolutionary invasion of shorter memory strategies.

This work can be used to classify plays of the IPD: data can be collected from actual interactions (in lab or in the field). Furthermore, this allows for a classification method similar to the notion of fingerprinting presented in [1]. Trained strategies can potentially be classified as extortionate or not or it could be possible to even constraint the reinforcement learning approaches that are becoming prevalent in the literature.

This work gives a mathematical process that could be akin to behaviours of suspicion of extortion. Behaviours that react to a sentiment of being extorted can be emulated by using the approach outlined here.
